We demonstrate that a fluidized bed of hard spheres during defluidization displays properties associated with formation of a glass. The final state is rate dependent, and as this state is approached, the bed exhibits heterogeneity with increasing time and length scales. The formation of a glass results in the arrest of macroscopic particle motion and thus the loss of fluidization. Microscopic motion persists in this state, but the bed can be jammed by application of a small increase in flow rate. Thus a fluidized bed can serve as a test system for studies of glass formation and jamming.

DOI: 10.1103/PhysRevLett.96.145702 PACS numbers: 64.70.Pf, 45.70.-n, 47.55.Kf, 81.05.Rm

Despite a century of study, there is no unified theory for the formation of a glass state from a liquid cooled below its freezing point (supercooled) [1,2]. However, some signatures of glass formation have been identified. One is the dependence of the volume of the glass on the cooling rate: the slower a liquid is cooled, the greater density it achieves when it forms a glass. Another signature is a rapid increase in a characteristic relaxation time (or viscosity) of the liquid during cooling as the glass transition temperature T_g is approached. In colloidal and hard sphere systems the transition is reached by increasing volume fraction ϕ rather than decreasing temperature; the transition occurs at $\phi_p \approx 0.58$ [3–5].

In liquids [6–9], colloids [9,10], and simulations [11–14] it has been observed that as the glass transition is approached, the system dynamics becomes increasingly heterogeneous. Both the size of spatially correlated regions and the time scale for rearrangement of these regions increase rapidly near the glass transition.

We examine a fluidized bed [15,16], which is a vertical column of particles with an upward flow of fluid that maintains the particles in motion. As the fluid flow rate Q is decreased, this nonequilibrium [17] system exhibits characteristic signatures of the equilibrium glass transition. We find that two different volume fractions are important in the loss of fluidization: $\phi_g = 0.582$, where bulk quantities change, and $\phi_a = 0.594$, where ϕ becomes nearly independent of Q and only small scale motion persists; this motion can be stopped by a slight increase in flow rate, jamming the system. Our observed ϕ_g is close to the volume fraction at which a glass transition is observed in other hard sphere systems [3–5,10]. The observed ϕ_a is close to the value obtained for slow defluidization of particles in a gas fluidized bed [18], and close to the volume fraction where the system has the maximal number of statistically independent regions [19].

Experiment.—Water flows upward at a volume flow rate Q through a vertical column of glass spheres in a square bore glass tube of cross sectional area $A=5.81~\rm cm^2$. There are 4×10^6 glass spheres with diameter $d=250~\pm$

8 μ m and density $\rho_p = 2.47$ g/cm³. Flow rate fluctuations are smaller than 0.3%. To obtain uniform flow, fluid passes into the bottom of the column through a nylon mesh (5 μ m weave, open area 0.75%, Nitex mesh, Sefar America). The average height h of the bed top surface above the distributor is measured to determine the average bed solid volume fraction, $\phi = M_p/\rho_p Ah$, where M_p is the total mass of the particles. We measure the fluid pressure drop ΔP from the bottom to the top of the bed; values are normalized by the buoyant weight of the grains. The dynamics of the bed are studied by imaging the side of the bed and by using diffusing wave spectroscopy (DWS) [20] to probe the interior of the bed.

Signatures of glass formation.—The dependence of ϕ on the ramping rate (Fig. 1) is similar to the dependence of glass volume on cooling rate in supercooled liquids that form glasses [1]. In a fluidized bed for sufficiently large Q,

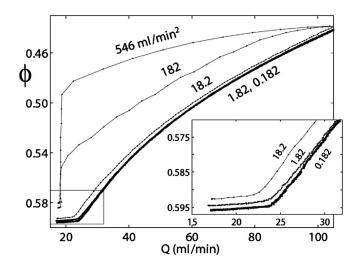

FIG. 1. The volume fraction achieved during defluidization depends on the ramp rate (cf. values next to the curves), just as in the glass transition. In the top two curves the ramping is so rapid that the final state is achieved through sedimentation. Inset: magnification of the region near the arrest transition at $\phi_a = 0.594$; only the three slowest ramp rates are shown.

the grains are mobile [21] and $\Delta P \cong 1$. However, as Q decreases, particle mobility decreases and ϕ increases until the defluidization transition is reached at ϕ_a (the knee of the curve in the inset of Fig. 1); ϕ_a decreases only 1% as the "cooling rate" dQ/dt is decreased by more than 2 orders of magnitude.

Another signature of glass formation is dynamical heterogeneity. As when other systems approach the glass state [6,8,10,11,14], the size of the mobile and immobile regions in the fluidized bed increases as ϕ increases [10], as shown by the images in Fig. 2(a) and by the correlation range ξ in Fig. 3(a), where ξ is given by the 1/e point of an azimuthal average of 2D autocorrelation of difference images separated by time ΔT . The heterogeneities observed both at the top and the side of the bed are similar to volcanos and channels observed in gas fluidized beds [22].

The decrease in ξ near ϕ_g is similar to the decrease in length scale of cooperative regions observed in colloid experiments [10] and lattice model simulations [23]. The decrease in ξ that we observe arises because the dynamics has slowed enough near ϕ_g so that no discernible motion occurs during the measurement time ΔT . Motion can be observed for increased ΔT , but then ξ remains close to zero until $\phi \approx \phi_g$ [cf. Fig. 3(a) [24]]; most particles in the bed have moved during this ΔT and thus the correlation measurement picks up only the minimum observable motion. The lifetime τ of mobile and immobile regions in-

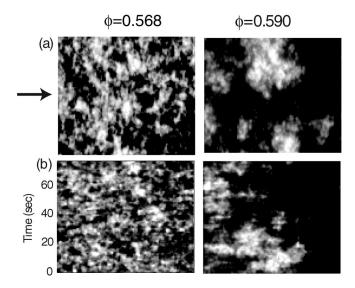

FIG. 2. (a) Dynamical heterogeneity: as ϕ increases, transiently immobile regions (black) and transiently mobile regions (white) grow in size. Each panel is the difference between two images $(1.5 \times 1.5 \text{ cm}^2)$ of the side of the bed taken $\Delta T = 0.25 \text{ s}$ apart. (b) Raster scans for the row of pixels indicated by an arrow in (a) show that the lifetimes of the correlated regions increase as ϕ increases. The flow rates for $\phi = 0.568$ and $\phi = 0.590$ were, respectively, 33.02 and 26.19 ml/min. In this figure and in Fig. 3 the data were obtained at ϕ values reached by decreasing Q at the slowest ramp rate in Fig. 1.

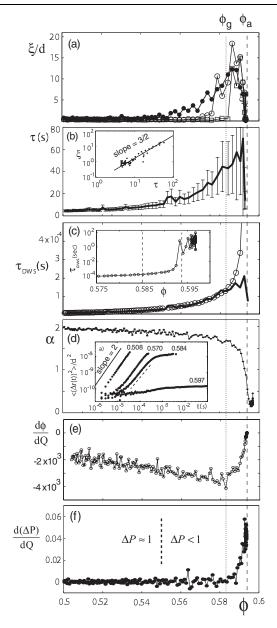

FIG. 3. Measurements on a fluidized bed reveal two transitions: a transition in bulk properties at $\phi_g = 0.582 \pm 0.004$ and an arrest transition at $\phi_a=0.594\pm0.003$ [24]. (a) An increase near ϕ_g in the spatial correlation length ξ of mobile regions [Fig. 2(a)], and a decrease in ξ beyond ϕ_g to $\xi = 0$ at ϕ_a . [ξ is shown for $\Delta T = 0.25 \text{ sec } (\bullet)$, 2.8 sec (\bigcirc) , and 50 sec (\square) .] (b) An increase in the average correlation time in bed images [Fig. 2(b)]. The inset shows a power law dependence of ξ on τ near ϕ_g . (c) An increase near ϕ_g in the decorrelation time $au_{\rm DWS}$ from the intensity autocorrelation function (1/e point) of transmitted laser light [20]. The bold solid curve, the correlation time from (b) scaled by 3×10^5 , begins to deviate from $\tau_{\rm DWS}$ at ϕ_g . The inset shows that at the arrest transition, au_{DWS} no longer increases. (d) A decrease beyond ϕ_g in the exponent α for the mean square displacement (MSD) for intermediate times indicated by the dashed line in the inset, which shows the time dependence of MSD. (e) An inflection in $d\phi/dQ$ at ϕ_g and a divergence in $d\phi/dQ$ as ϕ_a is approached. (f) An increase in $d(\Delta P)/dQ$ beyond ϕ_g and a peak at ϕ_a , where $d(\Delta P)/dQ$ becomes independent of Q.

creases as ϕ increases, as shown in Fig. 2(b) and in Fig. 3(b), where τ is obtained by averaging over all pixels (i, j) (for each pixel the time $\tau_{i,j}$ is given by the 1/e point of the time autocorrelation function of the intensity). The standard deviation of the distribution of decay times [denoted by vertical bars in Fig. 3(b)] also increases as ϕ increases; similar behavior has been found in a lattice model [23]. The slowing of the dynamics is similar to other glass-forming systems [1]. We find that the length and time scales for $\phi < \phi_g$ are linked by a power law, as shown in the inset of Fig. 3(b). A power law was also obtained in a study of a lattice model [23], but with an exponent value 1/4 rather than the 3/2 given by our observations. In contrast to [23] the length scale plotted in Fig. 3(b) is obtained for fixed $\Delta T = 0.25$ sec.

Additional signatures of glass formation are revealed by the bed behavior on short time scales. Measurements of the intensity-intensity correlation function $g^{(2)}(t)$ of light multiply scattered as it travels through the bed [25] yield the time scale $\tau_{\rm DWS}$ [Fig. 3(c)], which increases until $\phi = \phi_g$ with the *same* functional form as the decorrelation time of image pixel intensity τ [Fig. 3(b)]. The correspondence in the behavior for times differing by a factor of $\sim 10^5$ indicates that, as in other glass formers [1], the macroscopic and microscopic dynamics behave the same prior to the glass transition and become decoupled as the system forms a glass.

Information on particle motion at small length scales was obtained using diffusing wave spectroscopy (DWS) theory [20] to invert the autocorrelation curves and obtain $\langle \Delta r(t)^2 \rangle$, the mean square displacement (MSD) of the grains at times so short that particles moved only $\sim 0.01\%$ of their diameter. For $\phi \ll \phi_g$, the short time dynamics are well described by $\langle \Delta r(t)^2 \rangle \propto t^{\alpha}$ with $\alpha \approx 2$ [Fig. 3(d) inset], indicating that all grains undergo ballistic motion between collisions [21,26]. For $\phi \gtrsim 0.54$, as ϕ approaches ϕ_g , the curves develop a region with $\alpha < 2$ at short times, indicating that at these times the particles remain in contact with neighbors. However, at larger times, $\alpha \approx 2$ [cf. inset of Fig. 3(d)], indicating that the particles move ballistically. As ϕ approaches ϕ_g , the MSD develops a plateau region at longer times, indicating the particles are caged; caging has been observed in hard sphere systems that approach the glass state [4,10,12]. However, the plateau observed in our MSD measurements indicates a caging length of order $10^{-4}d$, 3 orders of magnitude smaller than what is observed in these systems. For $\phi > \phi_g$, the slope at intermediate times decreases, indicating that particles are no longer able to break from their cages, and α rapidly decreases [Fig. 3(d)]. For $\phi > \phi_a$, all particles are immobile on macroscopic length scales [Figs. 3(a)-3(c)].

The bulk properties of the bed change at ϕ_g : $d\phi/dQ$ reaches a minimum [Fig. 3(e)], and the pressure drop ΔP across the bed begins to decrease rapidly, dropping well below the buoyant weight of the bed [27]. This is shown by the derivative $d(\Delta P)/dQ$, which increases at ϕ_g until the

increase is arrested at ϕ_a [Fig. 3(f)], beyond which the bed has defluidized and ΔP becomes linear with Q, following Darcy's law [28]. We propose that the minimum in $d\phi/dQ$ and the increase of $d(\Delta P)/dQ$ beyond ϕ_g are further signatures of glass formation: once the bed begins to behave like a glass close to ϕ_g , the necessity for increasingly cooperative particle motion [10] makes it unable to continue to pack sufficiently (increase ϕ) in response to changes in Q as it would in the fluidized state where ΔP is maintained close to unity. Since the formation of a glass triggers the rapid drop in ΔP , which leads to the final macroscopic arrest of the bed at ϕ_a , we conclude that defluidization is a consequence of the hard sphere glass transition. This explains why ϕ_a seen in our water fluidized bed and the gas fluidized bed experiments of Ojha et al. [18] is independent of particle size, container aspect ratio, and fluidizing medium.

Jamming.—Even in the arrested state, microscopic motion persists, as shown in the time evolution of images of a line of scattered light [29] [Fig. 4(b)]. The intensity of each

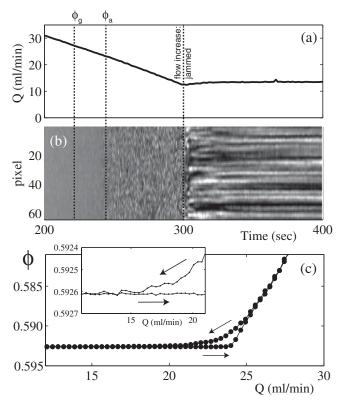

FIG. 4. Microscopic motion in the glass state is halted by a slight increase in Q, jamming the system. (a) Q is decreased (at 9.6 ml/min²) to 12.5 ml/min, at which point it is increased by 1 ml/min (indicated by the rightmost dashed line). ϕ_g is achieved at 27 ml/min (indicated by the leftmost dashed line) and ϕ_a is achieved at 23 ml/min (indicated by the middle line). (b) The speckle field, measured (30 ms exposure) along a line with each pixel corresponding to a single coherence area, becomes time independent after jamming occurs. (c) Hysteresis in ϕ for increasing and decreasing Q after an increase in Q at $Q \approx 8$ ml/min. The hysteresis disappears for $\phi > \phi_g$.

pixel fluctuates even for $\phi > \phi_a$, indicating that microscopic motion persists. However, for $\phi > \phi_g$ all microscopic motion can be jammed (stopped) by slightly increasing Q (for the conditions of our experiment, DWS can detect motion as small as ~ 1 nm for any scattering particle). The jamming presumably establishes the stress backbone of the system [30] and explains the hysteresis seen in Fig. 4(c). Once the system is jammed, increases and decreases in Q below the onset of fluidization [15] do not change ϕ . Such jamming has been associated with glass states [30–32] and has been studied in fluidized beds [33].

Conclusions.—We have shown that a fluidized bed exhibits essential features of glass formation: rate dependence on final state, dynamical heterogeneity, rapid increase in time scale, and jamming. Further, we propose that the hard sphere glass formation controls the defluidization of the bed: beyond ϕ_g the system cannot pack sufficiently to accommodate changes in flow and must therefore arrest at $\phi_a > \phi_g$ with ϕ_a independent of particle size, container aspect ratio [18], and fluidizing medium. The volume fraction transition values depend weakly on surface properties [19] and strongly on cohesive effects [27]. Finally, we speculate that the random loose packed volume fraction, $\phi_{\rm RLP} \approx 0.56$ [34], plays a role in the onset of heterogeneity, similar to the concept of onset transition observed prior to the glass transition [35].

A fluidized bed is a simple system that allows fine control, so it is an ideal system for studying glass and jamming transitions and for informing theory [36]. Further, understanding glass behavior in a fluidized bed can inform fluidized bed design, which is important in many industrial applications [15].
